3

Object-Oriented Programming

Lab Objective: Python is a class-based language. A class is a blueprint for an object that binds together specified variables and routines. Creating and using custom classes is often a good way to write clean, efficient, well-designed programs. In this lab we learn how to define and use Python classes. In subsequents labs, we will often create customized classes for use in algorithms.

Classes

A Python *class* is a code block that defines a custom object and determines its behavior. The **class** key word defines and names a new class. Other statements follow, indented below the class name, to determine the behavior of objects instantiated by the class.

A class needs a method called a *constructor* that is called whenever the class instantiates a new object. The constructor specifies the initial state of the object. In Python, a class's constructor is always named <code>__init__()</code>. For example, the following code defines a class for storing information about backpacks.

```
class Backpack:
    """A Backpack object class. Has a name and a list of contents.

Attributes:
    name (str): the name of the backpack's owner.
    contents (list): the contents of the backpack.

"""

def __init__(self, name):  # This function is the constructor.
    """Set the name and initialize an empty list of contents.

Parameters:
    name (str): the name of the backpack's owner.

"""
    self.name = name  # Initialize some attributes.
    self.contents = []
```

An *attribute* is a variable stored within an object. This Backpack class has two attributes: name and contents. In the body of the class definition, attributes are assigned and accessed via the name self. This name refers to the object internally once it has been created.

Instantiation

The class code block above only defines a blueprint for backpack objects. To create an actual backpack object, "call" the class name like a function. This triggers the constructor and returns a new *instance* of the class, an object whose type is the class.

```
# Import the Backpack class and instantiate an object called 'my_backpack'.
>>> from object_oriented import Backpack
>>> my_backpack = Backpack("Fred")
>>> type(my_backpack)
<class 'object_oriented.Backpack'>

# Access the object's attributes with a period and the attribute name.
>>> print(my_backpack.name, my_backpack.contents)
Fred []

# The object's attributes can be modified dynamically.
>>> my_backpack.name = "George"
>>> print(my_backpack.name, my_backpack.contents)
George []
```

NOTE

Every object in Python has some built-in attributes. For example, modules have a <code>__name__</code> attribute that identifies the scope in which it is being executed. If the module is being run directly, not imported, <code>__name__</code> is set to <code>"__main__"</code>. Therefore, any commands under an <code>if __name__</code> == <code>"__main__"</code>: clause are ignored when the module is imported.

Methods

In addition to storing variables as attributes, classes can have functions attached to them. A function that belongs to a specific class is called a *method*.

```
class Backpack:
    # ...
    def put(self, item):
        """Add 'item' to the backpack's list of contents."""
        self.contents.append(item) # Use 'self.contents', not just 'contents'.

def take(self, item):
        """Remove 'item' from the backpack's list of contents."""
        self.contents.remove(item)
```

The first argument of each method must be **self**, to give the method access to the attributes and other methods of the class. The **self** argument is only included in the declaration of the class methods, **not** when calling the methods on an instantiation of the class.

```
# Add some items to the backpack object.
>>> my_backpack.put("notebook")  # my_backpack is passed implicitly to
>>> my_backpack.put("pencils")  # Backpack.put() as the first argument.
>>> my_backpack.contents
['notebook', 'pencils']

# Remove an item from the backpack.  # This is equivalent to
>>> my_backpack.take("pencils")  # Backpack.take(my_backpack, "pencils")
>>> my_backpack.contents
['notebook']
```

Problem 1. Expand the Backpack class to match the following specifications.

- 1. Modify the constructor so that it accepts three total arguments: name, color, and max_size (in that order). Make max_size a keyword argument that defaults to 5. Store each input as an attribute.
- 2. Modify the put() method to check that the backpack does not go over capacity. If there are already max_size items or more, print "No Room!" and do not add the item to the contents list.
- 3. Write a new method called dump() that resets the contents of the backpack to an empty list. This method should not receive any arguments (except self).
- 4. Documentation is especially important in classes so that the user knows what an object's attributes represent and how to use methods appropriately. Update (or write) the docstrings for the __init__(), put(), and dump() methods, as well as the actual class docstring (under class but before __init__()) to reflect the changes from parts 1-3 of this problem.

To ensure that your class works properly, write a test function outside outside of the Backpack class that instantiates and analyzes a Backpack object.

```
def test_backpack():
    testpack = Backpack("Barry", "black")  # Instantiate the object.
    if testpack.name != "Barry":  # Test an attribute.
        print("Backpack.name assigned incorrectly")
    for item in ["pencil", "pen", "paper", "computer"]:
        testpack.put(item)  # Test a method.
    print("Contents:", testpack.contents)
    # ...
```

Inheritance

To create a new class that is similar to one that already exists, it is often better to *inherit* the methods and attributes from an existing class rather than create a new class from scratch. This creates a *class hierarchy*: a class that inherits from another class is called a *subclass*, and the class that a subclass inherits from is called a *superclass*. To define a subclass, add the name of the superclass as an "argument" at the end of the class declaration.

For example, since a knapsack is a kind of backpack (but not all backpacks are knapsacks), we create a special Knapsack subclass that inherits the structure and behaviors of the Backpack class, and adds some extra functionality.

```
# Inherit from the Backpack class in the class definition.
class Knapsack(Backpack):
    """A Knapsack object class. Inherits from the Backpack class.
    A knapsack is smaller than a backpack and can be tied closed.
   Attributes:
        name (str): the name of the knapsack's owner.
        color (str): the color of the knapsack.
        max_size (int): the maximum number of items that can fit inside.
        contents (list): the contents of the backpack.
        closed (bool): whether or not the knapsack is tied shut.
    def __init__(self, name, color, max_size=3):
        """Use the Backpack constructor to initialize the name, color,
        and max_size attributes. A knapsack only holds 3 item by default.
        Parameters:
            name (str): the name of the knapsack's owner.
            color (str): the color of the knapsack.
            max_size (int): the maximum number of items that can fit inside.
        Backpack.__init__(self, name, color, max_size)
        self.closed = True
```

A subclass may have new attributes and methods that are unavailable to the superclass, such as the closed attribute in the Knapsack class. If methods from the superclass need to be changed for the subclass, they can be overridden by defining them again in the subclass. New methods can be included normally.

```
def take(self, item):  # Override the take() method.
   """If the knapsack is untied, use the Backpack.take() method."""
   if self.closed:
        print("I'm closed!")
   else:
        Backpack.take(self, item)

def weight(self):  # Define a new method just for knapsacks.
   """Calculate the weight of the knapsack by counting the length of the string representations of each item in the contents list.
   """
   return sum([len(str(item)) for item in self.contents])
```

Since Knapsack inherits from Backpack, a knapsack object is a backpack object. All methods defined in the Backpack class are available to instances of the Knapsack class. For example, the dump() method is available even though it is not defined explicitly in the Knapsack class.

The built-in function <code>issubclass()</code> shows whether or not one class is derived from another. Similarly, <code>isinstance()</code> indicates whether or not an object belongs to a specified class hierarchy. Finally, <code>hasattr()</code> shows whether or not a class or object <code>has</code> a specified attribute or method.

```
>>> from object_oriented import Knapsack
>>> my_knapsack = Knapsack("Brady", "brown")
# A Knapsack is a Backpack, but a Backpack is not a Knapsack.
>>> print(issubclass(Knapsack, Backpack), issubclass(Backpack, Knapsack))
True False
>>> isinstance(my_knapsack, Knapsack) and isinstance(my_knapsack, Backpack)
True
# The put() and take() method now require the knapsack to be open.
>>> my_knapsack.put('compass')
I'm closed!
# Open the knapsack and put in some items.
>>> my_knapsack.closed = False
>>> my_knapsack.put("compass")
>>> my_knapsack.put("pocket knife")
>>> my_knapsack.contents
['compass', 'pocket knife']
# The Knapsack class has a weight() method, but the Backpack class does not.
>>> print(hasattr(my_knapsack, 'weight'), hasattr(my_backpack, 'weight'))
True False
# The dump method is inherited from the Backpack class.
>>> my_knapsack.dump()
>>> my_knapsack.contents
Γ٦
```

Problem 2. Write a Jetpack class that inherits from the Backpack class.

- 1. Override the constructor so that in addition to a name, color, and maximum size, it also accepts an amount of fuel. Change the default value of max_size to 2, and set the default value of fuel to 10. Store the fuel as an attribute.
- 2. Add a fly() method that accepts an amount of fuel to be burned and decrements the fuel attribute by that amount. If the user tries to burn more fuel than remains, print "Not enough fuel!" and do not decrement the fuel.
- 3. Override the dump() method so that both the contents and the fuel tank are emptied.
- 4. Write clear, detailed docstrings for the class and each of its methods.

Note

All classes are subclasses of the built-in object class, even if no parent class is specified in the class definition. In fact, the syntax "class ClassName(object):" is not uncommon (or incorrect) for the class declaration, and is equivalent to the simpler "class ClassName:".

Magic Methods

A magic method is a special method used to make an object behave like a built-in data type. Magic methods begin and end with two underscores, like the constructor <code>__init__()</code>. Every Python object is automatically endowed with several magic methods, which can be revealed through IPython.

```
In [1]: run object_oriented.py
In [2]: b = Backpack("Oscar", "green")
                    # Press 'tab' to see standard methods and attributes.
In [3]: b.
                   max_size take()
          color
          contents name
          dump()
                   put()
In [3]: b.__
                    # Press 'tab' to see magic methods and hidden attributes.
          __add__()
                              __getattribute__ __new__()
          __class__
                                                 __reduce__()
                              __gt__
                                                __reduce_ex__()
          __delattr__
                              __hash__
          __dict__
                              __init__()
                                                  __repr__
          __dir__()
                              __init_subclass__() __setattr__
          __doc__
                              __le__
                                                  __sizeof__()
                              __lt__()
                                                  __str__
          __eq__
                                                   __subclasshook__()
          __format__()
                              __module__
                                                   __weakref__
                              __ne__
          __ge__
```

Note

Many programming languages distinguish between *public* and *private* variables. In Python, all attributes are public, period. However, attributes that start with an underscore are hidden from the user, which is why magic methods do not show up at first in the preceding code box.

The more common magic methods define how an object behaves with respect to addition and other binary operations. For example, how should addition be defined for backpacks? A simple option is to add the number of contents. Then if backpack A has 3 items and backpack B has 5 items, A + B should return 8. To incorporate this idea, implement the <code>__add__()</code> magic method.

```
class Backpack:
    # ...
    def __add__(self, other):
        """Add the number of contents of each Backpack."""
        return len(self.contents) + len(other.contents)
```

Using the + binary operator on two Backpack objects calls the class's __add__() method. The object on the left side of the + is passed in to __add__() as self and the object on the right side of the + is passed in as other.

```
>>> pack1 = Backpack("Rose", "red")
>>> pack2 = Backpack("Carly", "cyan")

# Put some items in the backpacks.
>>> pack1.put("textbook")
>>> pack2.put("water bottle")
>>> pack2.put("snacks")

# Add the backpacks together.
>>> pack1 + pack2  # Equivalent to pack1.__add__(pack2).
3
```

Comparisons

Magic methods also facilitate object comparisons. For example, the <code>__lt__()</code> method corresponds to the < operator. Suppose one backpack is considered "less" than another if it has fewer items in its list of contents.

```
class Backpack(object)
    # ...
    def __lt__(self, other):
        """If 'self' has fewer contents than 'other', return True.
        Otherwise, return False.
        """"
        return len(self.contents) < len(other.contents)</pre>
```

Using the < binary operator on two Backpack objects calls __lt__(). As with addition, the object on the left side of the < operator is passed to __lt__() as self, and the object on the right is passed in as other.

```
>>> pack1, pack2 = Backpack("Maggy", "magenta"), Backpack("Yolanda", "yellow")
>>> pack1 < pack2
False
>>> pack2.put('pencils')
>>> pack1 < pack2  # Equivalent to pack1.__lt__(pack2).
True</pre>
```

Comparison methods should return either True or False, while methods like __add__() might return a numerical value or another kind of object.

Method	Arithmetic Operator	Method	Comparison Operator
add()	+	lt()	<
sub()	_	le()	<=
mul()	*	gt()	>
pow()	**	ge()	>=
truediv()	/	eq()	==
floordiv()	//	ne()	!=

Table 3.1: Common magic methods for arithmetic and comparisons. What each of these operations do, or should do, is up to the programmer and should be carefully documented. For more methods and details, see https://docs.python.org/3/reference/datamodel.html#special-method-names.

Problem 3. Endow the Backpack class with two additional magic methods:

- The __eq__() magic method is used to determine if two objects are equal, and is invoked
 by the == operator. Implement the __eq__() magic method for the Backpack class so
 that two Backpack objects are equal if and only if they have the same name, color, and
 number of contents.
- 2. The __str__() magic method returns the string representation of an object. This method is invoked by str() and used by print(). Implement the __str__() method in the Backpack class so that printing a Backpack object yields the following output (that is, construct and return the following string).

```
Owner: <name>
Color: <color>
Size: <number of items in contents>
Max Size: <max_size>
Contents: [<item1>, <item2>, ...]
```

(Hint: Use the tab and newline characters '\t' and '\n' to align output nicely.)

ACHTUNG!

Magic methods for comparison are **not** automatically related. For example, even though the Backpack class implements the magic methods for < and ==, two Backpack objects cannot respond to the <= operator unless __le__() is explicitly defined. The exception to this rule is the != operator: as long as __eq__() is defined, A!=B is False if and only if A==B is True.

Problem 4. Write a ComplexNumber class from scratch.

- 1. Complex numbers are denoted a+bi where $a,b \in \mathbb{R}$ and $i=\sqrt{-1}$. Write the constructor so it accepts two numbers. Store the first as self.real and the second as self.imag.
- 2. The *complex conjugate* of a+bi is defined as $\overline{a+bi}=a-bi$. Write a conjugate() method that returns the object's complex conjugate as a new ComplexNumber object.
- 3. Add the following magic methods:
 - (a) Implement __str__() so that a+bi is printed out as (a+bj) for $b \ge 0$ and (a-bj) for b < 0.
 - (b) The magnitude of a + bi is $|a + bi| = \sqrt{a^2 + b^2}$. The __abs__() magic method determines the output of the built-in abs() function (absolute value). Implement __abs__() so that it returns the magnitude of the complex number.
 - (c) Implement __eq__() so that two ComplexNumber objects are equal if and only if they have the same real and imaginary parts.
 - (d) Implement __add__(), __sub__(), __mul__(), and __truediv__() appropriately. Each of these should return a new ComplexNumber object.

Write a function to test your class by comparing it to Python's built-in complex type.

```
def test_ComplexNumber(a, b):
    py_cnum, my_cnum = complex(a, b), ComplexNumber(a, b)

# Validate the constructor.
if my_cnum.real != a or my_cnum.imag != b:
    print("__init__() set self.real and self.imag incorrectly")

# Validate conjugate() by checking the new number's imag attribute.
if py_cnum.conjugate().imag != my_cnum.conjugate().imag:
    print("conjugate() failed for", py_cnum)

# Validate __str__().
if str(py_cnum) != str(my_cnum):
    print("__str__() failed for", py_cnum)
# ...
```

Additional Material

Static Attributes

Attributes that are accessed through self are called *instance* attributes because they are bound to a particular instance of the class. In contrast, a *static* attribute is one that is shared between all instances of the class. To make an attribute static, declare it inside of the class block but outside of any of the class's methods, and do not use self. Since the attribute is not tied to a specific instance of the class, it may be accessed or changed via the class name without even instantiating the class at all.

```
class Backpack:
    # ...
brand = "Adidas"  # Backpack.brand is a static attribute.
```

```
>>> pack1, pack2 = Backpack("Bill", "blue"), Backpack("William", "white")
>>> print(pack1.brand, pack2.brand, Backpack.brand)
Adidas Adidas Adidas

# Change the brand name for the class to change it for all class instances.
>>> Backpack.brand = "Nike"
>>> print(pack1.brand, pack2.brand, Backpack.brand)
Nike Nike
```

Static Methods

Individual class methods can also be static. A static method cannot be dependent on the attributes of individual instances of the class, so there can be no references to self inside the body of the method and self is not listed as an argument in the function definition. Thus static methods only have access to static attributes and other static methods. Include the tag @staticmethod above the function definition to designate a method as static.

```
# Static methods can be called without instantiating the class.
>>> Backpack.origin()
Manufactured by Nike, inc.

# The method can also be accessed by individual class instances.
>>> pack = Backpack("Larry", "lime")
>>> pack.origin()
Manufactured by Nike, inc.
```

To practice these principles, consider adding a static attribute to the Backpack class to serve as a counter for a unique ID. In the constructor for the Backpack class, add an instance variable called self. ID. Set this ID based on the static ID variable, then increment the static ID so that the next Backpack object will have a different ID.

More Magic Methods

Consider how the following methods might be implemented for the Backpack class. These methods are particularly important for custom data structure classes.

Method	Operation	Trigger Function
bool()	Truth value	bool()
len()	Object length or size	<pre>len()</pre>
repr()	Object representation	repr()
getitem()	Indexing and slicing	<pre>self[index]</pre>
setitem()	Assignment via indexing	self[index] = x
iter()	Iteration over the object	<pre>iter()</pre>
reversed()	Reverse iteration over the object	reversed()
contains()	Membership testing	in

See https://docs.python.org/3/reference/datamodel.html#special-method-names for more details and documentation on all magic methods.

Hashing

A hash value is an integer that uniquely identifies an object. The built-in hash() function calculates an object's hash value by calling its __hash__() magic method.

In Python, the built-in **set** and **dict** structures use hash values to store and retrieve objects in memory quickly. If an object is *unhashable*, it cannot be put in a set or be used as a key in a dictionary. See https://docs.python.org/3/glossary.html#term-hashable for details.

If the __hash__() method is not defined, the default hash value is the object's memory address (accessible via the built-in function id()) divided by 16, rounded down to the nearest integer. However, two objects that compare as equal via the __eq__() magic method must have the same hash value. A simple __hash__() method for the Backpack class that conforms to this rule and returns an integer might be the following.

```
class Backpack:
    # ...
    def __hash__(self):
        return hash(self.name) ^ hash(self.color) ^ hash(len(self.contents))
```

The caret operator $\hat{}$ is a bitwise XOR (exclusive or). The bitwise AND operator & and the bitwise OR operator | are also good choices to use.

See $\texttt{https://docs.python.org/3/reference/datamodel.html#object._hash__$ for more on hashing.
